

Accounting for the Heterogeneity in Retirement Wealth*

Fang Yang[†]

State University of New York at Albany

April 2009

Abstract

This paper studies a quantitative dynamic general equilibrium life-cycle model where parents and their children are linked by bequests, both voluntary and accidental, and by the transmission of earnings ability. This model is able to match very well the empirical observation that households with similar lifetime earnings hold very different amounts of wealth at retirement. Earnings heterogeneity and borrowing constraints are essential in generating the variation in wealth at retirement among low lifetime earnings households, while inheritance heterogeneity generated by intergenerational links helps to generate the heterogeneity in wealth at retirement among high lifetime earnings households.

Keywords: Wealth Inequality; Retirement; Earnings Shocks; Bequest.

1 Introduction

Many papers document that households with similar characteristics, such as lifetime income, age, and family structure, hold very different amounts of wealth at retirement (see, among others, Hurst, Luoh and Stafford (1998), and Grafova, McGonagle and Stafford (2006)). Various economists (see, for example, Bernheim, Skinner and Weinberg (2001), and Hendricks (2007a)) argue that this feature of the data is inconsistent with most life-cycle models of consumption-saving behavior, and thus constitutes a challenge to such theories and their policy implications.

In particular, Venti and Wise (2000) and Hendricks (2007a) document that substantial wealth difference remains after controlling for lifetime earnings and age. At all levels of lifetime earnings, there is a large dispersion in the accumulated wealth at retirement: A significant fraction of high earnings households have relatively little wealth, and a substantial fraction of low earnings households have a lot.

In this paper, I quantify how much of the observed heterogeneity in wealth at retirement, after controlling for lifetime earnings, can be generated by a realistically parameterized model with incomplete markets and earnings shocks. The model that I am using mainly incorporates two basic forces, voluntary and accidental bequests, and productivity transmission, into an otherwise standard life-cycle model.¹ In this model, households face uninsurable labor-income risk, uncertain lifetimes, and borrowing constraints in the bonds market. Households save to self-insure against labor income shocks and life-span risk, for retirement, and possibly to leave bequests to their children. Households are ex-ante identical.² Wealth difference at retirement re-

¹This model extends De Nardi (2004) by allowing children to observe parents' states and incorporating a realistic Social Security system and a private pension system.

²I assume limited sources of heterogeneity, abstracting from ex-ante heterogeneity in wealth holdings by race (see for example Smith (1995), and Altonji and Doraszelski (2005)), by education (see for example Hubbard, Skinner and Zeldes (1995), and Cagetti (2003)), and by preference (see for example Krusell and Smith (1998), Samwick (1998), and Hendricks (2007b)), from ex-post heterogeneity in wealth holdings by marital status (see for example Cubeddu and Rios-Rull (2003), and Guner and Knowles (2003)), by children (see for example Scholz and Seshadri (2006)), and by rate of return (see

mains, after controlling for lifetime earnings, because households differ in the timing of earnings over the life cycle and in the amount and timing of inheritances received.

This incomplete-market model with earnings heterogeneity and inheritance heterogeneity can generate large wealth heterogeneity among households with similar lifetime earnings. The existence of borrowing constraints prevents households from smoothing consumption intertemporally. Two households might have the same lifetime earnings, but one might have positive earnings shocks when young and negative earnings shocks when old while the other has negative earnings shocks when young and positive earnings shocks when old. At retirement, those two households will hold amounts of wealth that differ substantially.

Inheritance adds another source of wealth heterogeneity among households with similar lifetime earnings. Some households might have inherited a large amount of assets. With a voluntary bequest motive, those who have inherited keep a large amount of assets to leave to their children, thus holding a substantial amount of wealth at retirement. Some households receive no inheritance and thus own less wealth. Inheritance heterogeneity endogenously determined in the model is not as large as in the data. Yet it is substantial enough to help to generate wealth variation among households with similar lifetime earnings.

I then decompose the effect of earnings heterogeneity and inheritance heterogeneity on wealth heterogeneity in the benchmark model. I find that, differences in the timing of earnings shocks can generate large heterogeneity in wealth at retirement among lower lifetime earnings households, who can rely more on pension wealth since pension wealth is a concave function of lifetime earnings. Differences in the timing and amount of inheritance help to generate large heterogeneity in wealth at retirement among higher lifetime earnings households, who on average receive more inheritances and are more

for example Guvenen (2006)).

likely to keep assets due to bequest motives.

To investigate the relative importance of two features, voluntary and accidental bequests and productivity transmission, I run several experiments. A model with bequest motives and without intergenerational transfer of productivity generates more variation in wealth at retirement among households with similar lifetime earnings than the benchmark model. The main reason is that, without intergenerational link of productivity, some households at the low lifetime earnings deciles receive unrealistically large amount of inheritances, weakening the correlation between lifetime earnings and retirement wealth. A model without bequest motives shows that intergenerational transfers of involuntary bequests and earnings ability are not sufficient to generate the observed variation in wealth at retirement. One reason is that accidental bequests along are not enough to generate large inheritance differences. The other reason is that, without an operative bequest motive, those who have inherited large estates from their parents will consume a large part of their inheritances before retirement. Finally, in a model without intergenerational transfers of both bequests and earnings ability, the only source of heterogeneity, the timing of earnings shocks, is not enough to generate the observed wealth heterogeneity among households with similar lifetime earnings.

This paper is related to the literature that examines the implications of different models on wealth dispersions at retirement age.³ Engen, Gale, Carroll and Laibson (1999), Engen, Gale and Uccello (2004), and Scholz, Seshadri and Khitatrakun (2006) study the adequacy of household retirement saving. Those papers abstract from the intergenerational links of bequests and earnings ability. Gokhale, Kotlikoff, Sefton and Weale (2001) abstract from voluntary bequest motives. Hendricks (2007a) argues that standard incomplete-market models with only earnings heterogeneity have dif-

³This paper builds on a large literature that attempts to account for the economy-wide wealth inequality (see, among others, Huggett (1996), Quadrini (2000), Casteneda, Diaz-Gimenez, and Rios-Rull (2003), De Nardi (2004), and Cagetti and De Nardi (2006)).

faculty matching the correlation between lifetime earnings and wealth at retirement, and adding inheritance differences only improves the quantitative results of such models marginally. Compared with Hendricks (2007a), my model generates much larger heterogeneity in retirement wealth holding among households with similar lifetime earnings. The main reason is the different treatment of bequests between my model and Hendricks's. Hendricks assumes that households receive bequests at the same age; I assume that the time of inheritance is uncertain and different. Hendricks assumes all bequests are accidental; I assume households are altruistic towards their descendants.

The paper is organized as follows. Section 2 presents some empirical results documenting heterogeneity of wealth at retirement among households with similar lifetime earnings. Section 3 presents the model and the calibration of the model. Section 4 shows the quantitative results of the benchmark model and investigates the relative importance of earnings heterogeneity and inheritance heterogeneity. Section 5 investigates the quantitative importance of intergenerational links. Section 6 concludes.

2 Empirical Findings

This section presents some empirical results from Venti and Wise (2000) and Hendricks (2007a) showing that, substantial wealth difference remains after controlling for lifetime earnings and age: Households with similar lifetime earnings hold diverse amounts of wealth at retirement age.

Venti and Wise (2000) use data from the Health and Retirement Study (HRS) for households whose heads were between age 51 to 61 in 1992. They use wealth of the household and lifetime earnings measured by historical earnings reported to Social Security Administration. They find that, at all levels of lifetime earnings, there is a large dispersion in the accumulated wealth at retirement. Very little of this dispersion can be explained by differences in individual circumstances that are out of the control

of the households. They argue, informally, that the dispersion of wealth at retirement must be attributed to differences in the amount that households choose to save.

Hendricks (2007a) uses data from the Panel Study of Income Dynamics (PSID) on wealth reported at age 65.⁴ Earnings consist of labor income (net of income tax payments and Social Security contributions) received by the household head and by the spouse, which include wages, salaries, bonuses, overtime payments, and the business part of labor income. Lifetime earnings are the presented value of earnings between the ages of 18 and 65, discounted to age 65.

Figure 1: Retirement wealth and lifetime earnings in the PSID

Figure 1 shows the scattered plot of log retirement wealth and log lifetime earnings from PSID. Wealth at retirement is strongly correlated with lifetime earnings: The correlation coefficient between lifetime earnings and wealth at retirement is 0.61. However, at all levels of lifetime earnings there is large dispersion in the accumulated wealth at retirement: A significant fraction of high earnings households have relatively little wealth and a significant fraction of low earnings households have a lot.

Figure 2 displays the Gini coefficient of retirement wealth for each lifetime earnings decile from Venti and Wise (2000) and Hendricks (2007a). We observe that, controlling

⁴SCF has a better coverage of high-earner and high-wealth households than PSID and HRS. However, as is shown in Juster, Smith and Stafford (1999), and Cagetti (2003), for lower quartiles, those data sets give similar information.

for age and lifetime earnings reduces wealth inequality. For example, in the PSID, the average of the Gini coefficients in wealth across lifetime earnings deciles is 0.54, compared with 0.62 in the full sample. However, there is still large wealth inequality after controlling for age and lifetime earnings: The Gini coefficients are all above 0.4. The degree of wealth inequality declines with lifetime earnings decile.

Figure 2: Gini coefficient of retirement wealth for each earnings decile

To check the robustness of those findings, Venti and Wise (2000) conduct regressions to control for household characteristics. Hendricks (2007a) restricts samples to contain only households with similar characteristics. The main findings are not affected by household characteristics such as numbers of children, marital breakups, self-employment, or stock holdings.

Those papers' findings thus indicate that households with similar lifetime earnings hold diverse amounts of wealth at retirement age, even when samples are restricted to exclude sources of wealth heterogeneity that are not related to earnings. Those features of the data constitute a challenge to our theories of saving behavior.

3 The Model

The economy is a discrete-time overlapping generations world with an infinitely-lived government. The government taxes labor earnings, capital income and estates, pays

Social Security benefits to retirees, and provides government consumption. There are idiosyncratic earnings shocks. These shocks are uninsurable: The only financial instrument is a one-period bond. Households cannot engage in unsecured borrowing; net assets must be non-negative. There is mortality risk but private annuity markets do not exist.⁵ Members of successive generations are linked by bequests and the children’s inheritance of part of their parent’s productivity. At age 20, each agent enters the model and starts consuming, working, and paying labor and capital income taxes. After retirement, the agent no longer works but receives interest from accumulated assets and benefits from Social Security and from defined benefit plan provided by the firm.

3.1 Demographics

During each model period, which is 5 years long, a continuum of people is born. Since there are no inter-vivos transfers, all agents start their working life with no assets.⁶ I denote age $t = 1$ as 20 years old, age $t = 2$ as 25 years old, and so on. At the beginning of period 4, the agent’s children are born, and four periods later (when the agent is 55 years old) the children are 20 years old and start working. The agents retire at $t = 10$ (when they are 65 years old) and die by the end of age $T = 14$ (before turning 90 years old). From $t = 10$ (when they are 65 years old), each person faces a positive probability of dying, given by $(1 - p_t)$. The probability of dying is exogenous and independent of other household characteristics. The population grows at rate n . Since the demographic patterns are stable, agents at age t make up a constant fraction of the population at any point in time.

⁵Although private annuity market does exist in the U.S., due to reasons such as the lack of actuarially fair prices, and the existence of bequest motives, the demand for annuities is quite low.

⁶Data from the HRS suggests that observed inter-vivos monetary transfers are fairly small (Cardia and Ng (2000)). Given the small size of observed inter-vivos monetary transfers, I doubt that this simplification would affect much the quantitative predictions of my model.

3.2 Government

The government taxes labor earnings, capital income and estates to finance the exogenous public expenditure, G , and to provide Social Security benefits to the retired agents. Income from labor is taxed at a flat rate τ_l .⁷ Income from capital is taxed at a flat rate τ_a . Government taxes bequests at the rate τ_b for the proportion above the exemption level ex_b .

The structure of the Social Security system is the following: Retired households receive Social Security benefits from the government each period until they die. The Social Security benefits that individuals receive are linked to their average lifetime earnings according to a piecewise linear function.

3.3 Technology

There is one type of good produced according to the aggregate production function $F(K; L) = K^\alpha L^{1-\alpha}$, where K is the aggregate capital stock and L is the aggregate labor input. The final goods can be either consumed or invested into physical capital. Physical capital depreciates at rate δ . Households rent capital and efficient labor units to the representative firm each period, and receive rental income at the interest rate r and wage income at the wage rate w .

The representative firm maintains a defined benefit plan, which is financed by contributions on each work's behalf. All workers face the same contribution rate τ_{DB} . Retired households receive pensions from defined benefit plan each period until they die. The pension benefits that individuals receive are linked to their average lifetime earnings according to a piecewise linear function.⁸

⁷In the model, labor earnings are estimated using after-tax earnings. Thus all the progressive features of the tax system are already reflected in the calibrated after-tax earnings distribution. I introduce a constant tax rate τ_l to balance the government budget.

⁸Scholz, Seshadri and Khitatrakun (2006) propose an alternative model of defined benefit plan, in which pension benefits are linked to individuals' average earnings in the past 5 year before retirement.

3.4 Consumer's Maximization Problem

3.4.1 Preferences

Individuals derive utility from consumption and from bequests transferred to their children upon death.⁹ Preferences are assumed to be time separable, with a constant discount factor β . The momentary utility function from consumption is of the constant relative-risk aversion class given by

$$(1) \quad U(c) = \frac{c^{1-\eta} - 1}{1-\eta}.$$

Following De Nardi (2004), the utility from bequest b is denoted by

$$(2) \quad \phi(b) = \phi_1(1 + b/\phi_2)^{1-\eta}.$$

The term ϕ_1 reflects the parent's concern about leaving bequests to his/her children, while ϕ_2 measures the extent to which bequests are luxury goods.¹⁰

3.4.2 Labor Productivity

In this economy, all agents of the same birth cohort face the same exogenous age-efficiency profile, ϵ_t . Each worker i also faces stochastic productivity shocks y_t^i , which follows a Markov process Q_y

$$\ln y_t^i = \rho_y \ln y_{t-1}^i + \mu_t^i, \quad \mu_t^i \sim N(0, \sigma_y^2).$$

This Markov process is the same for all households, so that there is no uncertainty over the aggregate labor endowment. The total productivity of a worker at age t is given by the product of the worker's age- t productivity shock and age- t deterministic efficiency index: $y_t^i \epsilon_t$.

To capture the intergenerational correlation of earnings, I assume the parent's pro-

⁹Note that this form of 'impure' bequest motive implies that an individual cares about the total bequests left to his/her children, but not about consumption of his/her children.

¹⁰With the specifications, bequests are luxury goods. The scalar 1 inside the parameters ensures that the marginal utility of small bequests is bounded, while the marginal utility of large bequests declines more slowly than the marginal utility of consumption.

ductivity shock at age 55 is transmitted to children at age 20 according to the following transition function Q_{yh}

$$\ln y_1^i = \rho_{yh} \ln y_{h,8}^i + \nu_1^i, \quad \nu_1^i \sim N(0, \sigma_{yh}^2).$$

What the children inherit is only their first draw; from age 20 on, their productivity y_t evolves stochastically according to Q_y .

3.4.3 The Household's Recursive Problem

In a stationary equilibrium, the interest rate is constant at r and the wage rate is at w .¹¹ I assume that children have full information about their parents' state and children solve their decision problems after observing their parents' decisions. Children infer the size of the bequests they are likely to receive based on this information. The household's state variables are given by $(t, a, y, \tilde{y}, S_p)$. The first four variables denote the agent's age, financial assets carried from the previous period, the agent's productivity, and cumulated average productivity, respectively. The last term S_p denotes the agent's parent's state variables and differs in each of the following four cases.

(i) From $t = 1$ to $t = 2$ (from 20 to 25 years of age), the agent survives for sure until next period and does not expect to receive a bequest because his/her parent is younger than 65.

$$(3) \quad V(t, a, y, \tilde{y}, a_p, y_p, \tilde{y}_p) = \max_{c, a'} U(c) + \beta E(V(t+1, a', y', \tilde{y}', a'_p, y'_p, \tilde{y}'_p))$$

subject to

$$(4) \quad c + a' = (1 - \tau_l)w\epsilon_t y + (1 + r(1 - \tau_a))a,$$

$$(5) \quad a' \geq 0, \quad c \geq 0,$$

$$(6) \quad \tilde{y}' = ((t-1)\tilde{y} + \epsilon_t y)/t,$$

$$(7) \quad \tilde{y}'_p = ((t+6)\tilde{y}_p + \epsilon_{t+7} y_p)/(t+7).$$

¹¹A formal definition of the stationary equilibrium is provided in Appendix 7.1.

At any subperiod, the agent's resources depend on asset holdings, a , and labor endowment, $\epsilon_t y$. Asset holdings pay a risk-free rate r and labor receives a real wage w . Average productivity for children and parents accumulates according to equations (6) and (7), respectively.

(ii) From $t = 3$ to $t = 7$ (from 30 to 50 years of age), the worker survives for sure until the next period. However, the agent's parent is at least 65 years old and faces a positive probability of dying at any period; hence, a bequest might be received at the beginning of the next period. Let $V^I(t, a, y, \tilde{y})$ and $V(t, a, y, \tilde{y}, a_p, \tilde{y}_p)$ denote the value function of a person whose parent is dead and alive, respectively. In the former case, a_p and \tilde{y}_p are not in the state space any more.

$$(8) \quad V^I(t, a, y, \tilde{y}) = \max_{c, a'} U(c) + \beta E(V^I(t+1, a', y', \tilde{y}'))$$

subject to (4), (5), and (6).

(9)

$$V(t, a, y, \tilde{y}, a_p, \tilde{y}_p) = \max_{c, a^+} U(c) + \beta E(p_{t+7} V(t+1, a^+, y', \tilde{y}', a'_p, \tilde{y}'_p) + (1-p_{t+7}) V^I(t+1, a', y', \tilde{y}'))$$

subject to (5), (6), and

$$(10) \quad c + a^+ = (1 - \tau_l) w \epsilon_t y + (1 + r(1 - \tau_a)) a,$$

$$(11) \quad a' = a^+ + b,$$

where a^+ denotes the financial assets at the end of the period before receiving bequests.¹²

(iii) The sub periods $t = 8$ to $t = 9$ (from 55 to 60 years of age) are the periods before retirement, during which no more inheritances are expected because the agent's parent is already dead by that time. The agent does not face any survival uncertainty.

$$(12) \quad V(t, a, y, \tilde{y}) = \max_{c, a'} U(c) + \beta E(V(t+1, a', y', \tilde{y}'))$$

subject to (4), (5), and (6).

¹²Since parents are retired, average productivity for parents, \tilde{y}_p , does not change over time.

(iv) From $t = 10$ to $t = 14$ (from 65 to 85 years of age), the agent does not work and does not inherit any more, but faces a positive probability of dying. In case of death, the agent derives utility from bequeathing his/her assets. Households receive Social Security benefits $P(\tilde{y})$ and pensions from defined benefit plan $DB(\tilde{y})$.

$$(13) \quad V(t, a, \tilde{y}) = \max_{c, a'} U(c) + \beta p_t (V(t+1, a', \tilde{y})) + (1 - p_t) \phi(b)$$

subject to (5) and

$$\begin{aligned} c + a' &= (1 + r(1 - \tau_a))a + P(\tilde{y}) + DB(\tilde{y}) \\ b &= a' - \tau_b * \max(a' - ex_b, 0). \end{aligned}$$

3.5 Calibration

Table 1 lists the parameters of the model. Some parameters are picked from other studies, the remaining parameters are chosen to match some relevant aggregate moments of the data.¹³

I set the rate of population growth, n , to the average value of population growth from 1950 to 1997 from the Council of Economic Advisors (1998). The p_t 's are the vectors of conditional survival probabilities for people older than 65 and is set to the mortality probabilities for people born in 1965 (Bell, Wade and Goss (1992)).

The deterministic age-profile of labor productivity ϵ_t is taken from Hansen (1993).¹⁴ The persistence ρ_y and variance σ_y^2 of the stochastic productivity process are estimated from PSID data (Altonji and Villanueva (2002)).¹⁵ The persistence is low and variance is high because this refers to income in a 5-year period. I take persistence ρ_{yh} of the productivity inheritance process from Zimmerman (1992), and variance σ_{yh}^2 from De Nardi (2004).

The capital income tax τ_a is set to be 20% (Kotlikoff, Smetters and Walliser (1999)).

¹³One period in this model corresponds to 5 years in real life, thus I adjust parameters accordingly.

¹⁴Since I impose mandatory retirement at the age of 65, I set $\epsilon_t = 0$ for $t > 9$.

¹⁵De Nardi (2004) provides a detailed discussion of the estimation process.

Parameters		Calibrations
Demographics		
n	annual population growth	1.2%
p_t	survival probability	see text
Endowment		
ϵ_t	age-efficiency profile	see text
ρ_y	AR(1) coefficient of 5-year productivity process	0.85
σ_y^2	innovation of 5-year productivity process	0.30
ρ_{yh}	AR(1) coefficient of productivity inheritance process	0.67
σ_{yh}^2	innovation of productivity inheritance process	0.37
Government policy		
τ_a	tax on capital income	20%
τ_b	tax on bequest	10%
ex_b	exemption level on bequest tax	40
G	government spending	0.18
$P(\tilde{y})$	Social Security income	see text
τ_l	tax on labor income	33%
Technology		
α	capital share in National Income	0.36
δ	annual depreciation rate of capital	0.06
$DB(\tilde{y})$	Pension from defined benefit plan	see text
τ_{DB}	Contribution rate to defined benefit plan	5.2%
Preference		
η	risk aversion coefficient	1.5
β	discount factor	0.96
ϕ_1	weight of bequest in utility function	-14.6
ϕ_2	shifter of bequest in utility function	12.7

Table 1: Parameters used in the benchmark model

The rate τ_b is the tax rate on estates that exceed the exemption level ex_b . I choose these two parameters from De Nardi (2004) who matches the observed ratio of estate tax revenues to GDP, and the proportion of estates that pay estate taxes. G is total government expenditure and gross investment excluding transfers, and is chosen to be 18% of GDP (Council of Economic Advisors (1998) for 1996).

The Social Security benefit is calculated to mimic the Old Age and Survivor Insurance component of Social Security system. The Social Security benefit is equal to

$$\left\{ \begin{array}{ll} 0.9\tilde{y}w & \tilde{y}w < 0.2 \\ 0.18 + 0.32(\tilde{y}w - 0.2) & 0.2 \leq \tilde{y}w < 1.24 \\ 0.5128 + 0.15(\tilde{y}w - 1.24) & 1.24 \leq \tilde{y}w \end{array} \right\}.$$

The bend points, expressed as average earnings, and marginal rates are from Huggett and Ventura (2000).¹⁶

I take α , the share of income that goes to capital, to be 0.36 (Prescott (1986), and Cooley and Prescott (1995)). I take depreciation to be 6% (Stokey and Rebelo (1995)). Given the calibration for the production function, the before-tax interest rate on capital net of depreciation r is 6%. The defined benefit is equal to

$$\left\{ \begin{array}{ll} 0 & \tilde{y}w < 0.56 \\ 0.50(\tilde{y}w - 0.56) & 0.56 \leq \tilde{y}w < 0.95 \\ 0.1950 + 0.30(\tilde{y}w - 0.95) & 0.95 \leq \tilde{y}w < 1.24 \\ 0.2820 + 0.23(\tilde{y}w - 1.24) & 1.24 \leq \tilde{y}w < 2.47 \\ 0.5649 + 0.10(\tilde{y}w - 2.47) & 2.47 \leq \tilde{y}w < 3.0 \\ 0.6179 + 0.02(\tilde{y}w - 3.0) & 3.0 \leq \tilde{y}w < 3.8 \\ 0.6339 + 0.01(\tilde{y}w - 3.8) & \tilde{y}w \geq 3.8 \end{array} \right\}.$$

The bend points, expressed as average earnings, and marginal rates are chosen to mimic the holding of defined benefits wealth by lifetime earnings from HRS reported in Scholz, Seshadri and Khitatrakun (2006).

I take the risk aversion coefficient, η , to be 1.5, from Attanasio, Banks, Meghir and Weber (1999), and Gourinchas and Parker (2002), who estimate it from consumption data. This value is in the commonly used range (1-5) in the literature.

I choose $\beta, \phi_1, \phi_2, \tau_{DB}$, and τ_l to match the ratio of wealth to after-tax earnings of 4.9 (Hendricks (2007a)), bequest-capital ratio of 0.88% (Gale and Scholz (1994)), the average bequest left at the lowest 80th percentile of 2.78 (Hurd and Smith (2001)), and to balance government budget and private pension budget.¹⁷

¹⁶The corresponding payroll tax rate that balances the Social Security funds budget is 10.3%. Since the model focuses on retirement benefits, this rate is comparable to payroll taxes excluding the Medicare and Disability Insurance (10.6%).

¹⁷I use distribution for single decedents instead of the one for all decedents. Typically a surviving spouse inherits a large share of the estate, consumes part of it, and only leaves the remaining to the couple's children.

4 Numerical Results

This section examines to what extent the quantitative incomplete-market life-cycle model, with earnings heterogeneity and inheritances heterogeneity, can account for the observed large wealth difference among households with similar lifetime earnings. I first solve for the equilibrium. Details about computation are provided in Appendix 7.2. I then simulate 200,000 households starting from age 20 drawn from the initial distribution. I define retirement wealth to be the wealth at age 65, and lifetime earnings to be the total earnings from age 20 to 60, discounted to age 65 using the after-tax interest rate. I will compare results from the model with those from the PSID reported in Hendricks (2007a).¹⁸ Then I decompose the effect of earnings heterogeneity and inheritance heterogeneity on variation in wealth at retirement.

4.1 Inheritance Distribution

The general equilibrium model with intergenerational links of bequests and productivity endogenously generates differences in the timing and amount of inheritances. To see how large the variation in inheritance is, Table 2 reports values for the inheritance distribution in the benchmark economy and in the PSID (Hendricks (2007a)). Inheritances are deflated and discounted to the year where the head is 50 years old. In the PSID, inheritances are highly unevenly distributed with a Gini coefficient of 0.89. The top 1% of the households receive 35% of all the inheritances and the top 1-5% of the households receive 31% of all the inheritances. 50% of the households receive very little or no inheritance during their life time. The model generates a skewed inheritance distribution with a Gini coefficient of 0.86. 50% of the households receive no inheritance during their life time. The top 1% of the households receive 19% of the total

¹⁸Appendices 7.3 and 7.4 show the distribution of lifetime earnings, and the wealth distribution for the whole economy and for households at retirement age.

inheritance, and the top 1-5% of the households receive 35% of the total inheritance.

	Top percentile (%)							Gini
	1	1-5	5-10	10-20	20-30	30-50	50-100	
PSID	35	31	14	13	5	2	0	0.89
Benchmark	19	35	20	17	6	2	0	0.86

Table 2: Lorenz curve of inheritance distribution

Modeling the transmission of earnings ability across generations and treating bequests as luxury goods are essential to match the observed skewness in the inheritance distribution. First, because the marginal utility from bequeathing is finite at zero bequests, wealth-poor households will choose not to leave any bequest at the last stage of their life cycle. This helps to generate a large fraction of households without any inheritance. Secondly, some large inheritances are transmitted across generations because of the voluntary bequests. Because the marginal utility of bequests declines more slowly than the marginal utility of consumption, the richest households have strong bequest motives to save some assets for their children even when very old. When there is a positive correlation between parents and children, their offspring are more likely to be earnings-rich and thus tend to leave more wealth to their offspring, thus generating a skewed inheritance distribution.

	1-2	3-4	5-6	7-8	9-10
PSID	14	6	22	17	41
Benchmark	7	11	17	24	40

Table 3: Fraction of inheritances received by lifetime earnings decile (%)

To see how the inheritances are distributed by lifetime earnings, I present in Table 3, fraction of lifetime inheritances (in percentage) received by households in each lifetime earnings decile. In the PSID (Hendricks (2001)), inheritance is unevenly distributed across lifetime earnings deciles. Households in the top 2 lifetime earnings deciles receive 41% of the total inheritance. The model generates an increasing rela-

tion between inheritance and lifetime earnings. Modeling the transmission of earnings ability across generations and a highly correlated earnings process along the lifetime is key in generating this pattern.¹⁹

4.2 Wealth Inequality and Lifetime Earnings

I now look at the relationship between retirement wealth and lifetime earnings. To measure how large are the wealth differences between earnings-rich and earnings-poor households, I show in Figure 3, the mean retirement wealth at each lifetime earnings decile, normalized by average household after-tax earnings. In the PSID, the earnings-rich households on average hold more wealth than the earnings-poor households. The model does a very good job in matching the mean retirement wealth observed in the data for each earnings decile. In this model, households with higher lifetime earnings will save more than households with lower lifetime earnings due to the facts that bequest is a luxury good and benefits from Social Security and from defined benefit plan follow a concave function of lifetime earnings.

Figure 3: Mean of retirement wealth for each earnings decile (benchmark model)

¹⁹The monotonicity relation is weaker in the data. This might due to the fact that, in reality each married individual might receive inheritances multiply times from his/her own parents and from the parents of the spouse. Parental wealth is imperfectly correlated since the degree of assortative matching between spouses is not strong.

In the benchmark model with earnings heterogeneity and inheritance heterogeneity, substantial wealth heterogeneity remains after controlling for lifetime earnings and age. Figure 4 illustrates this using the Gini coefficients of retirement wealth for each lifetime earnings decile. We notice two important features. First, after controlling for age and lifetime earnings, there is still large wealth inequality in the model: The Gini coefficients in all earnings deciles in the benchmark economy are all above 0.3. Second, the degree of wealth inequality declines as lifetime earnings increases, as is observed in the data. For example, in the model the Gini coefficient is 0.66 for the 1st earnings decile and is 0.49 for the 5th decile. The model economy matches the wealth inequality for the lower deciles quite well but underestimates wealth inequality for the highest two deciles a bit.

Figure 4: Gini coefficient of retirement wealth for each lifetime earnings decile (benchmark)

To better gauge the amount of wealth dispersion at retirement generated by the model, Figures 5 compares the retirement wealth distributions for the 2nd, 5th, and 9th lifetime earnings deciles in the model with those in the data, where wealth is normalized by average household after-tax earnings. The model successfully replicates the fact that households with similar lifetime earnings hold diverse amounts of wealth. At each lifetime earnings decile, households in the lower wealth deciles hold very little wealth while households in the higher wealth deciles hold much more wealth. For example, a large fraction of households in the 2nd earnings decile hold almost no wealth. The

(a) 2nd lifetime earnings decile.

(b) 5th lifetime earnings decile.

(c) 9th lifetime earnings decile.

Figure 5: Distribution of wealth (benchmark model)

model generates skewed wealth distribution comparable to the data for the 2nd and 5th lifetime earnings deciles. Among households in the 9th lifetime earnings decile in the model, most people but the richest hold more wealth than in the data.

Table 4 compares some statistics summarizing the relationship between retirement wealth and lifetime earnings in the PSID with those in the benchmark economy. The model with earnings heterogeneity and inheritance heterogeneity can generate large wealth heterogeneity within lifetime earnings deciles. The correlation between retirement wealth and lifetime earnings (0.78) is positive and only slightly higher than that in the data (0.61). After controlling for age and lifetime earnings, the average of Gini

coefficients of retirement wealth within lifetime earnings deciles (0.47) is still quite high.

Both earnings and wealth in the data may be subject to measurement error. The fact that Venti and Wise (2000) and Hendricks (2007a) obtain similar results based on alternative data sources suggests that measurement error does not affect the empirical results much. To further address the issue of measurement error, I add random noise into the sample simulated from the model. I assume that for each household, the measured lifetime earnings is the product of the simulated lifetime earnings in the model multiplied by a random variable which is normally distributed with mean 1 and standard deviation 0.1. Similarly, random noise is added to the measured wealth at retirement. The random variable added to lifetime earnings is uncorrelated with the one added to wealth. The results are shown in Table 4. Adding random noise weakens the correlation between lifetime earnings and retirement wealth slightly. However, the average Gini coefficient barely changes. The reason is that, by grouping households into deciles, rather than looking at each household, some random noise averages out.

	Corr(W, E)	Mean Gini	Gini
PSID	0.61	0.54	0.62
Benchmark	0.78	0.47	0.62
Adding measurement error	0.77	0.47	0.62

Table 4: Relationship between retirement wealth and lifetime earnings

Compared with Hendricks (2007a), the benchmark economy generates much larger heterogeneity in retirement wealth holding within lifetime earnings deciles. In his model with one-time bequest drawn from a skewed distribution, there is a high correlation between retirement wealth and lifetime earnings (0.82) and a low average Gini coefficient (0.39). There are two important reasons for the differences in findings. First, in Hendricks (2007a), although bequests are drawn from the actual skewed distribution of bequests in PSID, households receive inheritance at the same age and the distribu-

tion of inheritance is approximated on a 5-point grid. As a consequence, inheritance heterogeneity is limited. Second, without voluntary bequest motives, those households who have inherited large amount consume a large part of the inheritance before retirement, reducing the wealth differences at retirement due to inheritance. In my model, although the endogenously generated inheritance distribution is not as skewed as in the data, households receive different amount of inheritances at different time and hold on more wealth due to operative bequest motives, which generates more heterogeneity in retirement wealth among households with similar lifetime earnings.

4.3 The Effect of Earnings Heterogeneity

In the benchmark model, retirement wealth inequality arises, among household with similar lifetime earnings, because households differ in the timing of earnings over the life cycle and in the amount and timing of inheritance received. Let us now try to understand the effect of earnings heterogeneity on the heterogeneity in retirement wealth.

A simple life-cycle model without earnings uncertainty and without borrowing constraints predicts a perfect correlation between lifetime earnings and retirement wealth. Adding earnings uncertainty and borrowing constraints breaks the perfect correlation, since the timing of positive or negative shocks differs among household with identical lifetime earnings.

Suppose two households have the same lifetime earnings, but one has positive earnings shocks when young and negative earnings shocks when old, the other has the reverse. The household with positive earnings shocks when young would save more in the earlier ages to buffer against negative earnings shocks later. Then he/she suffers negative earnings shocks later, he/she uses assets to finance consumption, resulting in low level of retirement wealth. The household with negative earnings shocks when

young anticipates high earnings in the future and would like to borrow to finance consumption but cannot. When he/she gets positive earnings shocks later, he/she saves most of them for retirement, and ends up holding a relatively large amount of wealth at retirement.

		Age									
		20-25	25-30	30-35	35-40	40-45	45-50	50-55	55-60	60-65	65
1	Shocks	1	1	1	1	1	2	3	5	5	
	Earnings	15	19	21	23	24	51	103	479	448	
	Assets	0	0	0	0	1	3	13	47	270	508
2	Shocks	3	3	3	2	2	1	0	0	1	
	Earnings	62	79	91	49	51	24	11	10	22	
	Assets	0	7	21	40	40	40	34	25	13	3
3	Shocks	3	3	3	3	5	5	5	5	5	
	Earnings	62	79	91	99	494	495	490	479	448	
	Assets	0	7	21	40	65	270	508	697	955	1118
4	Shock	5	4	4	4	4	3	3	2	0	
	Earnings	297	165	191	207	215	104	103	49	10	
	Assets	0	105	144	197	270	317	317	317	270	168

Table 5: Simulation of earnings and assets (in \$1000)

Table 5, row 1 and 2, show the simulated shocks, 5-year earnings, and assets holding at the beginning of each period for two households in the 3rd earnings decile with the same discounted lifetime earnings of \$1,850,000. Their parents are identical so their expectations of bequests are the same. Neither of them receives any bequests. But because of the different timing of earnings, the 1st household has retirement assets of \$508,000, 169 times as big as the 2nd household has (\$3,000). Table 5, row 3 and 4, show the simulated paths for two households in the 8th earnings decile with the same discounted lifetime earnings of \$6,200,000. The 3rd household has retirement assets 7 times as big as the 4th household has.

In summary, households with negative earnings shocks when young and positive earnings shocks later, hold a relatively large amount of wealth at retirement, than households with positive earnings shocks when young and negative earnings shocks

later. This holds for all earnings deciles. But the relative difference in wealth holdings is higher among lower earnings households (row 1 vs row 2) than higher earnings households (row 3 vs row 4).

This comparison indicates that, earnings heterogeneity caused by the different timing of earnings plays a more important role in generating heterogeneity on retirement wealth among households in the lower earnings deciles. The main reason is that benefits from Social Security and defined benefit plan follow a concave function of lifetime earnings. Households in all earnings deciles use assets to finance consumption when suffer negative earnings shocks later in life. Households in the lower earnings deciles, use more assets to finance consumption and carry fewer assets into retirement, since they anticipate higher pension wealth relative to current assets. On the contrary, households in the higher earnings deciles, use less assets to finance consumption and carry more assets into retirement, since they anticipate lower pension wealth relative to current assets.

4.4 The Effect of Inheritance Heterogeneity

Now I show the effect of inheritance heterogeneity on retirement wealth. I compare wealth distributions of 65-year-old households, in the 2nd, 5th and 9th lifetime earnings deciles, that did and did not inherit. The results are shown in Figure 6. At each decile, those who never inherited hold less wealth than those who have inherited, and the difference increases as wealth decile increases. The reason is, with operative bequest motives, those who have inherited hold a large part of the inheritances upon retirement age.

We also notice that inheritance heterogeneity plays a more important role for the higher earnings deciles: The difference between two distributions of retirement wealth increases by lifetime earnings decile. For example, those two distributions of retirement

Figure 6: Distribution of wealth at retirement (benchmark model)

wealth for the 2nd earnings decile differ after the 30th percentile, while those two distributions of retirement wealth for the 9th earnings decile differ since the 10th percentile. One reason is that, since bequest is modeled as a luxury good, households in the high lifetime earnings deciles, holding relatively more wealth, tend to leave more wealth to their offspring by carrying relatively more wealth towards retirement. Households in the low lifetime earnings deciles, holding relatively less wealth and thus less willing to leave bequests, consume more fraction of inheritance before retirement. The other reason is that, as is shown in Table 3, there is a positive correlation between lifetime inheritance and lifetime earnings: Those who have high lifetime earnings are more likely to inherit large estates.

5 Decomposition

The benchmark model adds two basic forces, voluntary and accidental bequests, and productivity transmission, into an otherwise standard model. To understand the relative importance of those two features, I run several experiments. First, I look at the model where parents care about leaving bequests to their children but there is no intergenerational transfer of productivity. Then, I look at a model where parents do

not care about bequests but there is intergenerational transfers of accidental bequests and productivity. Finally, to see how much wealth inequality can be generated by the life-cycle structure when only earnings uncertainty is activated, I turn off all intergenerational links and assume accidental bequests are equally redistributed among 50-year-old people.²⁰ In each case, I recalibrate β accordingly to target the same wealth-earnings ratio.

5.1 No Productivity Transfers

I now look at the model where parents care about leaving bequests to their children but there is no intergenerational transfer of productivity. Table 6, row three shows that in this case the correlation between retirement wealth and lifetime earnings is 0.74, compared with 0.78 in the benchmark economy. Although the Gini coefficient of retirement wealth is lower than that in the benchmark, the mean Gini coefficient of retirement wealth within lifetime earning deciles is higher than that in the benchmark.

	Corr(W, E)	Mean Gini	Gini
Benchmark	0.78	0.47	0.62
No productivity transfers	0.74	0.50	0.60
No bequest motives	0.83	0.40	0.57
No links	0.85	0.33	0.54

Table 6: Relationship between retirement wealth and lifetime earnings

Compared with the benchmark model, the model with bequest motives and without intergenerational transfer of productivity generates more heterogeneity of retirement wealth among households with similar lifetime earnings. The first reason is that, even without intergenerational transfer of productivity, voluntary bequest motives are

²⁰This is an extended version of Huggett (1996). It incorporates a realistic Social Security system and a private pension system.

enough to generate large variation in inheritances: The total bequest left (B/K) is quite similar to the benchmark economy, and the inheritance distribution is quite skewed (Table 7, row two). The second reason is that, with an operative bequest motive, those who inherited large estates from their parents will consume only a small part of their inheritances by the age of 65. Thus the heterogeneity of inheritance adds a lot to the heterogeneity of retirement wealth. The third reason is that, without intergenerational link of productivity, inheritances are evenly distributed by lifetime earnings decile, which is against what is observed in the data (Table 3). Some households at the low lifetime earnings deciles receive unrealistically large amount of inheritances, weakening the correlation between lifetime earnings and retirement wealth.

	Top percentile (%)						Gini	B/K(%)
	1	1-5	5-10	10-20	20-30	30-50		
Benchmark	20	35	20	17	6	2	0.86	0.88
No Prod. Trans.	19	35	20	17	6	3	0.85	0.83
No Beq. Motive	18	32	19	19	8	4	0.83	0.56

Table 7: Lorenz curve of inheritance distribution

5.2 No Bequest Motives

I now look at the model where parents do not care about leaving bequests to their children but there is intergenerational transfer of productivity. Accidental bequests, if any, are inherited by the children of the deceased. Table 6, row four shows that in this case, the correlation between retirement wealth and lifetime earnings is higher than in the benchmark. Control for age and lifetime earnings reduces a larger part of the observed wealth inequality: The average Gini coefficient of retirement wealth within lifetime earnings deciles is 0.40, compared with 0.47 in the benchmark.

This comparison shows that the unequal distribution of involuntary bequests and intergenerational transfer of earnings ability are not sufficient to generate the observed

heterogeneity of retirement wealth. One reason is that accidental bequests are not enough to generate large difference in inheritances: The total bequest left (B/K) is much smaller and inheritance distribution is not as skewed as in the benchmark model (Table 7, row three). The other reason is that, without an operative bequest motive, those who have inherited large estates from their parents will consume a large part of their inheritances before retirement.

5.3 No Intergenerational Links

In the model without intergenerational transfer of bequests and earnings ability, accidental bequests are equally redistributed, thus the only source of heterogeneity is the timing of earnings shocks. Table 6, row five shows that in this model the correlation between retirement wealth and lifetime earnings (0.85) is much stronger than in the benchmark economy. The average Gini coefficient of retirement wealth within lifetime earnings deciles (0.33) is much lower than that in the benchmark. The comparison indicates that the timing of earnings shocks and the existence of borrowing constraints in the bonds market along are not enough to generate the observed large wealth heterogeneity among households with similar lifetime earnings.

6 Conclusions

Empirical studies using micro data find that there is large heterogeneity in retirement wealth among households with similar lifetime earnings, and raise doubts about the ability of a standard life-cycle model of saving behavior to reproduce the observed facts.

I use a quantitative, incomplete-market, life-cycle, general equilibrium model in which parents and their children are linked by voluntary bequests and by the trans-

mission of earnings ability. I show that this model with earnings heterogeneity and inheritance heterogeneity generates a substantial amount of heterogeneity in retirement wealth among households with similar lifetime earnings. This suggests that a properly specified life-cycle model with intergenerational transfer of earnings ability and bequests captures the fundamental determinants of households saving and wealth accumulation.

I also investigate the quantitative relevance of earnings heterogeneity, and inheritance heterogeneity, respectively, in causing variation in retirement wealth among households with similar lifetime earnings. I find that, while earnings heterogeneity and borrowing constraints are essential to generate the heterogeneity in retirement wealth among low lifetime earnings households, inheritance heterogeneity generated by intergenerational links is crucial to explain the variation in retirement wealth among high lifetime earnings households.

This paper abstracts from housing. Housing is the single largest investment made by most consumers over their life time. As is shown in Yang (forthcoming), abstracting from housing might bias the study of life-cycle consumption and assets accumulation behavior. It will be interesting to extend this model to look at the effect of earnings heterogeneity and inheritance heterogeneity on wealth heterogeneity in an environment with housing.

7 Appendix

7.1 Definition of the stationary equilibrium

I focus on an equilibrium concept where factor prices and age-wealth distribution are constant over time. Each agent's state is denoted by x . An equilibrium is described as follows.

Definition 1 *A stationary equilibrium is given by government tax rates, transfers, and spending $(\tau_l, \tau_a, \tau_b, ex_b, P(\tilde{y}), G)$; an interest rate r and a wage rate w ; defined benefit*

policies $(\tau_{DB}, DB(\tilde{y}))$; value functions $V(x)$, allocations $c(x)$, $a'(x)$; and a constant distribution of people $m^*(x)$, such that the following conditions hold:

(i) Given government tax rates and transfers, the interest rate, the wage rate, and defined benefit policies, the functions $V(x)$, $c(x)$ and $a'(x)$ solve the described maximization problem for a household in a state x .

(ii) m^* is the invariant distribution of households over the state variables for this economy.²¹

(iii) All markets clear.

$$C = \int cm^*(dx), \quad K = \int am^*(dx), \quad L = \int \epsilon y m^*(dx), \quad C + (n + \delta)K + G = F(K; L).$$

(iv) The price of each factor is equal to its marginal product.

$$r = F_1(K, L) - \delta, \quad w = \frac{F_2(K, L)}{1 + \tau_{DB}}.$$

(v) The defined benefit pension budget is balanced at each period.

$$\int I_{t>9} DB(\tilde{y}) m^*(dx) = \tau_{DB} w L.$$

(vi) The government budget is balanced at each period.

$$G + \int I_{t>9} P(\tilde{y}) m^*(dx) = \tau_a r \int am^*(dx) + \tau_l w L + \int \tau_b (1 - p_t) I_{t>9} \max(a' - ex_b, 0) m^*(dx).$$

7.2 Computation of the Model

I discretize both the productivity and the productivity inheritance processes to six-state Markov chains according to Tauchen and Hussey (1991). Since I want the possible realizations for the initial inherited productivity level to be the same as the possible realizations for productivity during the lifetime, I choose the quadrature points jointly for the two processes. The resulting grid points for the productivity process y are [0.1464, 0.3356, 0.7002, 1.4283, 2.9801, 6.8306]. The transition matrix for Q_y is given by

$$\begin{bmatrix} 0.6099 & 0.3537 & 0.0357 & 0.0007 & 0.0000 & 0.0000 \\ 0.1307 & 0.5327 & 0.3026 & 0.0333 & 0.0006 & 0.0000 \\ 0.0086 & 0.1974 & 0.5193 & 0.2528 & 0.02175 & 0.0001 \\ 0.0002 & 0.0218 & 0.2528 & 0.5193 & 0.1974 & 0.0086 \\ 0.0000 & 0.0006 & 0.0333 & 0.3026 & 0.5327 & 0.1307 \\ 0.0000 & 0.0000 & 0.0007 & 0.0357 & 0.3537 & 0.6099 \end{bmatrix}.$$

²¹I normalize m^* so that $m^*(X) = 1$, which implies that $m^*(\chi)$ is the fraction of people alive that are in a state χ .

The transition matrix for Q_{yh} is given by

$$\begin{bmatrix} 0.3668 & 0.4788 & 0.1426 & 0.0116 & 0.0002 & 0.0000 \\ 0.0922 & 0.4240 & 0.3855 & 0.0928 & 0.0054 & 0.0000 \\ 0.0134 & 0.1887 & 0.4615 & 0.2899 & 0.0454 & 0.0011 \\ 0.0011 & 0.0454 & 0.2899 & 0.4615 & 0.1887 & 0.0134 \\ 0.0000 & 0.0054 & 0.0928 & 0.3855 & 0.4240 & 0.0922 \\ 0.0000 & 0.0002 & 0.0116 & 0.1426 & 0.4788 & 0.3668 \end{bmatrix}.$$

The transition matrices also induce an initial distribution of earnings.

The distribution of accumulated productivity at each age is approximated on a grid of 36. The state space for asset holdings is discretized. Using this grid, I can store the value functions and the distribution of households as finite-dimensional arrays.

For a given set of parameters, I solve for the steady state equilibrium as follows:

1. Guess an initial value of τ_l and τ_{DB} , and interest rate r , use the equilibrium conditions in the factor markets to obtain the wage rate w .
2. Solve the approximated optimal consumption and saving plans recursively.
3. Guess an initial joint distribution of parents and children at the beginning of the life cycle, compute the associated stationary distribution of households.
4. Compute the implied joint distribution of parents and children at the beginning of the life cycle. If the distributions converge, go to step 5; otherwise go to step 3.
5. Given the stationary distribution and prices, check weather all markets clear and weather the government budget and defined benefit pension budget are balanced. If so, an equilibrium is found. If not, go to step 1.

7.3 Distribution of Lifetime Earnings

Table 8 compares values for the lifetime earnings distribution for the benchmark economy with those in the PSID (Hendricks (2007a)). The model replicates the skewness of lifetime earnings distribution. This is not one of the features matched by construction, and can be seen as evidence of the ability of the model to replicate the realistic distribution of lifetime earnings.

	Gini	Top percentile (%)							
		1	1-5	5-10	10-20	20-40	40-60	60-80	80-100
PSID	0.32	4.4	9.5	9.1	15.5	24.5	18.0	12.3	6.6
Benchmark	0.39	4.0	12.3	11.8	17.4	23.4	15.4	10.2	5.5

Table 8: Lorenz curve of lifetime earnings (benchmark model)

Mean lifetime earnings at each decile, in the data and in the model, normalized by average lifetime earnings, is plotted in Figure 7. The model does a good job in matching lifetime earnings for each decile reported in the PSID. Lifetime earnings in the HRS, measured by the present value of Social Security earnings, are more evenly distributed than those in the PSID. The extreme low lifetime earnings for the lower

two deciles is caused by the fact that some persons in these deciles were employed in sectors not covered by the Social Security system and thus reported zero Social Security earnings. Lifetime earnings for the highest deciles in the HRS are subject to top-coding and thus are lower than in the PSID.

Figure 7: Mean of lifetime earnings for each earnings decile

7.4 Wealth Distribution

Table 9, row one, reports values for the wealth distribution for the benchmark economy. The U.S. data on the wealth distribution is from Hendricks (2007a) who uses 1994 wave of PSID. In the PSID, wealth is highly unevenly distributed with a Gini coefficient of 0.76. The top 1% of the households hold 23% of the total wealth. The model generates a skewed wealth distribution that is comparable with the data except for the top 1% of the wealth. The fraction of wealth held by the richest 1% is 12% in the model, compared with 23% in the PSID.²²

		Top percentile (%)						
		Gini	1	1-5	5-10	10-20	20-40	40-60
All	PSID	0.76	22.8	22.5	14.4	16.8	16.3	6.4
	Benchmark	0.74	12.1	26.3	18.5	19.8	16.8	5.47
Age 65	PSID	0.62	15.7	18.3	13.8	17.0	18.8	10.2
	Benchmark	0.62	7.4	19.4	16.6	20.9	20.9	9.7

Table 9: Distribution of wealth (benchmark model)

Table 9, row two, compares values for the wealth distribution at retirement for the benchmark economy with the U.S. data. Wealth at retirement is less unevenly distributed than wealth for the whole economy both in the data and in the model: In the benchmark the Gini coefficient of wealth at retirement is 0.62, compared with

²²An income process that implies very large earnings risk for the highest-income earners is key in matching wealth dispersion (Castaneda, Diaz-Gimenez and Rios-Rull (2003), and Cagetti and De Nardi (2006)). My model misses this key element thus could not match the fraction of wealth held by the richest 1%.

0.74 in the whole sample. This shows that a large amount of wealth dispersion in the economy is due to differences in age. The model generates a skewed retirement wealth distribution that is comparable with the data, except for the top 1% of the wealth holding.
